June 2026
Version 1.0 (CHFT v6/v2 Architectures)

Abstract

Autoregressive Transformer-based models have revolutionized Natural Language Processing (NLP) but suffer from a fundamental bottleneck: the computational and memory cost of the self-attention mechanism scales quadratically ($O(N^2)$) with context length, making key-value memory storage (KV-Cache) infeasible for massive sequences on low-power hardware.

We introduce **Complex Holographic Field Theory (CHFT)**, an alternative neural architecture based on Complex Symbolic Vectors in Hilbert Space (Vector Symbolic Architectures / Holographic Reduced Representations) and Continuous Associative Memories (Modern Hopfield Networks). CHFT reduces the memory cost of context representation to a constant $O(1)$ size, compressing the entire sequence history into a single complex-phase hypervector.

We showcase two research paradigms. In Paradigm 1 (CHFT v6, 768-dimensional), CHFT proved to be **3.6x faster** in training, required **50.2% less VRAM**, and resolved repetitive loops natively (boosting generation diversity by +20.0pp) against a baseline Transformer. In Paradigm 2 (CHFT v2, 16k-dimensional), we show that scaling the phase space solves vector superposition crosstalk, achieving an exceptional next-token prediction Accuracy@1 of **87.88%** on the TinyStories dataset after resolving a critical inference distribution shift.

1 Introduction and Motivation

The classical Transformer architecture computes attention by explicitly comparing every token to all previous ones. While this guarantees exact predictive accuracy, it imposes severe hardware limitations:

1. **Growing VRAM Consumption:** The KV-Cache grows linearly with processed tokens, limiting context window scalability on local edge devices.
2. **Slow Inference at Scale:** The quadratic computational complexity ($O(N^2)$) slows down autoregressive decoding as sequence length increases.

CHFT proposes to solve this via wave interference physics and holographic algebra. Instead of storing a list of historical vectors (KV-Cache), CHFT recursively “superposes” all previous tokens and their positions into a single, constant-dimension (D) continuous phase representation. When predicting the next token, the model performs associative memory retrieval based on the geometric properties of the complex Hilbert space.

2 Mathematical Foundations of CHFT

The CHFT architecture refines classical holographic representations by introducing quantum wavefunction principles, dispersive positional operators, and multi-head routing filters.

2.1 Quantum Wavefunction Normalization (QuantumNorm) and Born's Rule

Instead of employing standard deep learning normalization heuristics, CHFT normalizes the context state vector Ψ in Hilbert space using quantum probability conservation (L_2 norm):

$$\Psi_{\text{norm}} = \frac{\Psi}{\|\Psi\|_2} \quad (1)$$

This ensures that relative phases (phase coherence) are perfectly preserved. To measure the similarity between the accumulated context state and the vocabulary keys K_v , we project using **Born's Rule**:

$$\text{sim}_v = \frac{|\langle K_v, \Psi \rangle|}{\sqrt{D}} \quad (2)$$

The use of the complex modulus ($|\cdot|$) guarantees **U(1) Gauge Invariance**, making retrieval robust against global phase rotations of the context hypervector.

2.2 Dispersive Positional Wave Binding

To distinguish word order without destroying the superposition, each token is bound to a complex phase phasor that is rotated based on its positional distance p using a dispersive quadratic equation:

$$\theta_p = p \cdot \omega_1 + p^2 \cdot \omega_2 \quad (3)$$

where ω_1 and ω_2 are learnable frequency parameters. This mimics wave propagation in dispersive media, enabling the model to learn natural memory decay or attentional focus.

2.3 Multi-Head Phase Gating

To filter out the background crosstalk noise inherent to high-dimensional superposition, we split the D -dimensional phasors into H independent sub-vectors ("heads"). Each head dynamically computes its own phase attenuation:

$$g_h = \sigma(\text{ComplexLinear}_h(\Psi_{\text{norm}})) \quad (4)$$

This acts as a selective interference filter, isolating and amplifying semantically significant information while suppressing noise.

2.4 Soft Residual Holographic Feed-Forward Network (H-FFN)

To inject non-linear expressiveness into the holographic space without corrupting the geometric orthogonality of the complex phasors, we apply an expansive feed-forward network with GELU activation as a soft residual step:

$$\Psi_{\text{next}} = \Psi_{\text{prev}} + \alpha \cdot \text{FFN}(\Psi_{\text{prev}}) \quad (5)$$

where $\alpha = 0.15$ is a damping factor that prevents phase degradation.

3 Experimental Results and Benchmarks

We evaluated the CHFT architecture across two distinct paradigms designed to showcase its performance envelope.

3.1 Paradigm 1: CHFT v6 (Efficiency Benchmark)

Paradigm 1 measures raw resource footprints against a standard 1-layer Transformer. Both models shared identical hyperparameters (1,000 TinyStories, 64-token context length, 768-dimensional embedding space, batch size of 256, 5 training epochs on an RTX 3060 GPU).

Table 1: Paradigm 1: CHFT v6 (768-Dim) vs. Local 1-Layer Transformer

Comparison Metric	Transformer (Baseline)	CHFT v6	Impact / Difference
Accuracy@1 (Exact)	37.10%	28.17%	-8.93pp (Lossy superposition)
Perplexity (PPL)	23.27	48.69	+25.42 (Less deterministic)
Diversity Score (TTR)	28.9% (Severe loops)	48.9%	+20.0pp (Fluid generation)
Peak VRAM Memory	2239.1 MB	1124.6 MB	-50.2% (Half the footprint)
Training Time	13.5 minutes	3.7 minutes	-72.6% (3.6x speedup)

3.2 Paradigm 2: CHFT v2 (High-Capacity Semantic Scaling)

Paradigm 2 demonstrates how scaling the complex phasor dimension ($D = 16,384$) resolves vector superposition crosstalk. Under a 10-epoch training run on 3,000 stories using early-stopping with patience of 2, the high-capacity CHFT v2 model achieved exceptional next-token alignment.

Table 2: Paradigm 2: High-Capacity CHFT v2 vs. 124M Parameter Target LLM

Metric	Baseline Freq	CHFT v2 (16k-Dim)	Standard LLM (124M Target)
Accuracy@1	6.45%	87.88%¹	70.00%
Perplexity (PPL)	7,559.00	1.86	1.12
Diversity Score	0.0%	70.7%	8.0% – 12.0%

4 The Inference Normalization Mismatch Fix

In early stages of the high-capacity run, the model exhibited low perplexity but generated a random, unintelligible jumble of words (“word soup”). We identified and resolved a major distribution shift between training and inference:

- **The Mismatch:** During training, the context vectors Ψ were normalized using **Complex LayerNorm** and scaled by dividing by $\sqrt{D}$. However, during text generation, the iterative Hopfield attractor query (`refine_query`) normalized using a standard L_2 Norm ($\frac{\text{refined}}{\|\text{refined}\|_2}$).
- **The Solution:** We updated `refine_query` and `query_topk` in `model.py` to dynamically accept an optional normalization function `ln_fn`. In `generate.py`, we now feed the codebook’s Complex LayerNorm (`codebook.ln`) directly into the Hopfield query attractor.

This aligned training and inference mathematical spaces, boosting text diversity to **70.7%** and unlocking highly coherent language generation.

5 Conclusion and Future Work

CHFT does not aim to compete directly in high-reasoning tasks of frontier models. Instead, it redefines the boundary between **accuracy, memory, and computational cost**. Future work will focus on:

1. **Hybrid H-Transformers:** Combining classical Transformers for short-term reasoning with a CHFT channel for infinite background memory.
2. **Sub-Crosstalk Dimensional Scaling:** Exploring scaling laws beyond $D = 32,768$ to test if crosstalk decay asymptotically closes the remaining accuracy gap.
